

EFFECTS OF BORDER PRICE CHANGES ON AGRICULTURAL WAGES AND EMPLOYMENT IN MEXICO

SILVIA PRINA*

Case Western Reserve University, Cleveland, OH, USA

Abstract: This paper measures the impact of North American Free Trade Agreement–induced real border price changes of Mexican imports and exports on wages and employment of agricultural workers in Mexico. I find that changes in real border prices of crops did not affect agricultural wages. On the other hand, increases in the real price of vegetables (main agricultural export) were associated with an increase in employment in the cultivation of vegetables, whereas the drop in the real price of corn (main agricultural import) reduced the employment in the corn sector. This is in line with the predictions of neoclassical trade theory: in the absence of mobility costs or sector-specific skills, factors moved smoothly from import-competing sectors into export-competing sectors. 1 INTRODUCTION

Trade theory predicts that product market integration affects domestic labor markets through changes in relative product prices. Consequently, product price movements have been used extensively to estimate the potential effects of trade liberalisation on labour markets (Leamer and Levinsohn, 1995). Given the heated discussion about the potential effects of trade liberalisation of agricultural commodities (Anderson *et al.*, 2005; McMillan *et al.*, 2006; Tokarick, 2008; World Bank, 2008), it is of great interest to study how product price changes affect labour in the agricultural sector. Nevertheless, to date, there are few empirical studies on the impact of openness to trade on wage earners in the agricultural sector. Previous studies on the impact of trade on wages and employment in developing

countries have focused on the manufacturing sector¹ and have mostly considered unilateral trade liberalisations.² However, bilateral or multilateral trade agreements could have different effects than unilateral trade liberalisations. In fact, when a mutual reduction in trade barriers takes place, markets might broaden, as greater trade is promoted among the parties to the agreement, causing competition and specialisation to increase.³

This paper looks at the North American Free Trade Agreement (NAFTA) to study how wages and employment in the agricultural sector in Mexico responded to border price changes induced by trade liberalisation. 1 January 2008 marked the culmination of NAFTA's 14-year transition to free trade between Mexico, the USA and Canada. Given Mexico's opening to agricultural trade, its proximity to the USA and the importance of its agricultural sector, Mexico is an ideal candidate for an analysis of the impact of border price changes on the agricultural labour market.

As shown by McMillan *et al.* (2006) and Prina (2011), NAFTA-induced tariff cuts caused a reduction in the real Mexican border price of corn, an imported commodity and an increase in the real Mexican border price of fruits and vegetables, which are exported commodities.⁴ I look at the impact of NAFTA-triggered border price changes of crops imported from the USA and exported to the USA on agricultural workers in Mexico. I relate the intertemporal variation in the real Mexican border price of corn, tomatoes and melons to variation in wages and employment of landless workers engaged in agricultural activities. An important caveat is that not all border price changes in the data stem from product market integration; other sources could be exchange rate movements or transaction costs (Engel and Rogers, 1996; Gopinath *et al.*, forthcoming 2011). However, to the extent that trade liberalisation affects the price of a commodity,⁵ this analysis illustrates the potential impact of integration on agricultural labour.⁶

I use border price data from the US Department of Agriculture, Foreign Agricultural Service and individual and municipality level data from the Mexican National Employment Surveys [*Encuesta Nacional de Empleo* (ENEs)] collected in 1991, 1993 and 1995–2000. The detail of the data allows for a more disaggregated analysis and enables to control for differences across individuals and municipalities that may be correlated with changes in wages and employment. Currie and Harrison (1997) show the importance of using microdata to control for within sector characteristics when analysing the impact of trade reform on employment. Moreover, the use of border prices of both imports and exports enables me to account both for price reductions because of increased import competition and for beneficial effects of increases in the prices of exports.

¹Porto (2008) estimates the impact on Argentinian wages and unemployment in case of a world agricultural trade liberalisation.

²See Goldberg and Pavcnik (2004) and Harrison (2006) for an excellent review; Galiani and Sanguinetti (2003) for Argentina; Attanasio *et al.* (2004), and Goldberg and Pavcnik (2005) for Colombia; Robertson (2004), Feliciano (2001), Hanson and Harrison (1999), and Revenga (1997) for Mexico; Currie and Harrison (1997) for Morocco; Goh and Javorcik (2005) for Poland.

³In addition, a large fraction of today's world trade occurs in regional trading arrangements providing some degree of preferential access.

⁴Also, Nicita (2009) finds that tariff liberalisation in Mexico during the 1989–2000 period decreased the price of a basket of agricultural goods.

⁵Robertson (2004) shows that in Mexico, changes in prices are consistent with the changes in tariffs triggered by the trade liberalisation that occurred during the 1986–1999 period.

⁶An alternative approach to study the impact of NAFTA on agricultural wages and employment would be to use changes in *ad valorem* tariffs as an instrument for border prices, instead of using border prices directly. Unfortunately, this approach is infeasible because of the nature of the trade restriction regime. In fact, the agricultural goods considered are under different trade restrictions (a quota before NAFTA, and a tariff and a quota after NAFTA for corn, a specific tariff for tomatoes and an *ad valorem* tariff for melons). Thus, to convert all these different trade restrictions into *ad valorem* tariff equivalents, the price of each agricultural good needs to be used.

Several papers that study the impact of trade reforms on wages and employment in the industrial sector in developing countries show almost no impact on wages and small effects on employment (Wacziarg and Wallack, 2004; Papageorgiou *et al.*, 1991). The most popular explanation for the lack of a response is the presence of restrictive labour regulations that inhibit both labour mobility and wage flexibility. For Mexico, Feliciano (2001) finds that the trade reforms between 1986 and 1990 had no statistically significant impact on relative wages or relative employment in the manufacturing sector. She attributes her results to the difficulty of firing workers under Mexican labour law. Revenga (1997) also suggests that the small labour market response found in Mexico and Morocco might be caused by labour regulations. Aguayo-Tellez *et al.* (2010), looking at the effects of trade liberalisation policies in Mexico on women's market outcomes for the 1990–2000 period, find that the gender wage ratio remained stable and that female employment increased. In the agricultural sector, where most contracts are informal and most workers are temporary, we would expect large shifts in employment from one crop to another. Another possible explanation for the lack of an employment response is the presence of imperfect competition, with fewer players and high barriers to entry. Currie and Harrison (1997) show that this is the case for Morocco during the 1980s; firms adjusted to trade reforms by reducing profit margins and raising productivity, rather than by reducing employment. Again, this does not seem a plausible explanation for the agricultural sector, which is characterised by many farmers and low barriers to entry.

The results of my study suggest that labour mobility and flexibility of rural labour markets insulated workers from any adverse impact. In fact, changes in agricultural border prices do not seem to affect wages. This is what would be expected in a standard competitive market with easy mobility across sectors (such as corn, fruits or vegetables) because tasks are mostly unskilled, and there is little likelihood of sector-specific skills. In contrast, changes in agricultural border prices tend to affect employment: increases in the real price of vegetables (main agricultural export) are associated with an increase in employment in the cultivation of vegetables, whereas the drop in the real price of corn (main agricultural import) reduces employment in the corn sector. These results stand out when the analysis is conducted at the regional level, considering border, central and southern Mexican states separately. In fact, the response of employment to price increases varies with regional exposures to trade openness and regional characteristics. In particular, the NAFTA-induced drop in the real price of corn seems to have decreased employment in the corn sector in both border and central regions, and the border region was subject to a more substantial impact. Also, the NAFTA-induced increase in the real price of tomatoes seems to have raised employment in the cultivation of vegetables in the central states and decreased employment in the cultivation of corn and fruits in the border states. Furthermore, employment in the southern states does not seem to respond to real price changes. These results emphasise the importance of accounting for regional differences. Most previous studies do not consider that states far away from the border might be less affected by trade liberalisation. Goods that are traded in well-connected regions are not necessarily traded in other regions. Furthermore, there are significant differences in the quality of soil and distance and connection to the US border at the regional level (Levy, 2004; Levy *et al.*, 2002).

The following section briefly illustrates the changes in trade restrictions caused by NAFTA and portrays the agricultural trade between Mexico and the USA. Section 3 describes the individual and municipality data and the data on border prices of agricultural commodities that span the 1989–2005 period. Section 4 outlines the empirical strategy to measure the impact of changes in border prices that were triggered by NAFTA on agricultural wages and employment in Mexico. Finally, Section 5 summarises the results and concludes.

Figure 1. Mexican corn imports

2 AGRICULTURAL TRADE BETWEEN MEXICO AND THE USA AND NAFTA

Agricultural trade plays a crucial role in USA–Mexico economic relations despite the uneven size of the two economies. Mexican agriculture is a much more significant factor in the Mexican economy than US agriculture is in the US economy. Agriculture contributes 10 per cent to Mexico’s gross domestic product and employs about 22 per cent of the labour force, which amounts to about 8 million workers. In contrast, in the USA, agriculture accounts for only 2 per cent of GDP and employs about 2.7 per cent of the labour force, which is slightly less than 4 million workers.

The United States is Mexico’s most significant agricultural trading partner, whereas Mexico and Canada are the largest agricultural trading partners of the USA. US–Mexico agricultural trade is largely complementary, that is, the USA tends to export different commodities to Mexico than Mexico exports to the USA.

US exports of agricultural goods to Mexico are led by grains, with corn being the leading commodity, followed by rice, wheat, barley, potatoes and apples. During the 1989–1993 period, corn shipments to Mexico were low, whereas for the 1994–2004 period, US exports of corn soared to 6 per cent per year.⁷ As shown in Figure 1, US corn exports to Mexico account for almost all Mexican corn imports.

Agricultural Mexican exports to the USA are led by vegetables and fruits. Considering vegetables, their exports increased at 0.8 per cent annually during the 1989–1993 period. This is a very small rate compared with the 6.2 per cent yearly increase in the period post NAFTA (1994–2004). As shown in Figure 2, Mexican vegetable exports to the US account for about 65 per cent of US vegetable imports. Tomatoes are the leading export crop. As illustrated in Figure 3, more than 85 per cent of the tomatoes imported from the USA come from Mexico. Considering fruits, Mexican exports rose at 2.8 per cent per year between 1989 and 1993 and at 4.8 per cent per year after that. As shown in Figure 4, Mexican fruit exports to the USA account for about 20 per cent of US fruit imports. Melons are the leading export crop. As illustrated in Figure 5, around half of the melons imported by the USA come from Mexico.

Mexico’s opening started in the early 1980s with a reduction of some trade restrictions on exports and continued when Mexico became a full member of the General Agreement

⁷U.S. exports of corn to Mexico include both yellow and white corn. Mexican corn farmers typically grow white corn, which is used to make food products. Yellow corn is typically used to feed animals. However, there is some substitutability between yellow and white corn. Food-grade yellow corn is used to make corn flakes, chips, beer and other foods, and white corn can be used as animal feed (Zahniser and Coyle, 2004).

Figure 2. US vegetable imports

Figure 3. US tomatoes imports

on Tariffs and Trade in 1985. However, no major changes in the structure of border protection of agricultural products were undertaken until the NAFTA took effect on 1 January 1994. With NAFTA, the structure of border protection for Mexico’s agricultural sector was radically transformed. The aim of NAFTA was to eliminate all agricultural tariffs and quantitative restrictions on trade between the USA and Mexico. Many tariffs were eliminated immediately, with the others being phased out over periods of 5, 10 or 15 years. This implies that agricultural products became duty-free on 1 January 1998, 2003 or 2008.

Considering reductions in the Mexican tariff for corn imported from the USA, Prina (2011) finds that a 1 per cent decrease in the tariff caused a statistically significant decrease in its border price by 0.20 per cent after controlling for inflation in Mexico. Similarly, the findings of McMillan *et al.* (2006), suggest that corn producer prices for Mexican farmers fell as a result of NAFTA. Considering reductions in the US restrictions on imports of

Figure 4. US fruit imports

Figure 5. US melons imports

tomatoes and melons from Mexico, Prina (2011) finds that a 1 per cent decrease in the tariff caused an increase in border price of 0.20 per cent for tomatoes and 0.10 per cent for melons. Thus, there is some evidence that NAFTA increased the border price of tomatoes and melons (main agricultural exports) and reduced the border price of corn (main agricultural import). These changes in border prices could impact wages and employment of agricultural workers. The following sections investigate the nature of this effect.

3 DATA DESCRIPTION

The data at the individual and municipality level come from the National Employment Surveys ENE in Mexico. The ENE surveys were collected in 1991, 1993 and 1995–2000. Despite the fact that they have been performed at irregular intervals, they are comparable

in terms of the sampling frame, the sampling methodology, the timing, and the questionnaires used. The surveys are representative at the national level, and for 1996, 1998, and 2000, the surveys also are representative at the state level. They were undertaken using stratified sampling during the second quarter of each survey year. The size of the sample varies from year to year. Finally, the dataset is not a panel, but a repeated cross-section, as each subject was interviewed only once.

Along with each ENE survey, an Agricultural Supplement was carried out for those individuals who participated in agricultural activities. The ENE surveys and the Agricultural Supplement contain information on demographics, education and employment, which include data on weekly wages and number of hours worked. Also, by using information on farmers and workers belonging to each municipality, I can compute variables at the municipality level, such as an indicator of the land distribution, the fraction of land allocated to each crop category and the proportion of irrigated land.

As wage variable, I use individual hourly wages, calculated using data on weekly wages and weekly hours worked by worker. As employment variable, I consider the fraction of hours allocated to each crop category in each municipality. Given the nature of the data, which do not follow individuals over time, I believe this is the best measure of employment for the purposes of the analysis.

The border price dataset spans 1989–2005 and has information on the main agricultural goods exported from Mexico to the USA and for the main agricultural commodities imported by Mexico from the USA. I build it using the unit values of imports or exports as monthly border prices.⁸ Unit values are computed as the custom values divided by quantities. These data are taken from the US Department of Agriculture, Foreign Agricultural Service.⁹ The level of commodities aggregation is at the Foreign Agricultural Trade of the United States level, which aggregates HS 10-digit codes. The unit values, in US dollars, are deflated using the Producer Price Index at the farm level from the US Bureau of Labor Statistics and converted into Mexican pesos using the monthly exchange rate from the Central Bank of Mexico (Banco de Mexico).

I merge the individual and municipality data with the border price dataset. The surveys contain information regarding the different sectors in which agricultural workers are employed: corn, vegetables, fruits, and other crops. Therefore, I consider a unique border price for each group. In particular, for the categories “corn,” “vegetables” and “fruits,” I use the border prices of corn, tomatoes and melons, respectively. This is a reasonable choice because these are the most important goods produced in the grain, fruit and vegetable categories. In addition, tomatoes and melons are the leading crops imported to the USA for vegetables and fruits, respectively, whereas corn is the primary exported grain from the USA.¹⁰

Finally, because the surveys were conducted in the second quarter of each year, I compute the average prices using the monthly prices of April, May and June. The final outcome is a dataset consisting of about 10 years of data on border prices, agricultural workers and key characteristics at the municipality level.

Table 1 reports basics summary statistics for individual and municipality variables for Mexico and by regions. An agricultural worker is paid, on average, 10.4 Mexican pesos per

⁸By definition, the border price is the import (c.i.f.) or export (f.o.b.) price of a commodity used for calculating the market price, measured at the farm gate level. An implicit border price may be calculated as the unit value of imports or exports (Glossary of Agricultural Policy Terms, OECD).

⁹These data are originally collected by the Census Bureau of the US Department of Commerce.

¹⁰Another possibility would be to consider an average border price whose weight is given by the amount produced either at the national or state level. I discarded this possibility, because, for some of these goods, the border price is not available.

Data from the ENE datasets and Agricultural Supplement, 1991–2000.

hour.¹¹ At both national and regional levels, there are not strong wage differentials by sectors (corn, fruits, vegetables and other crops). Only corn wages appear slightly lower than the others. This seems reasonable because no particular skills are required to work in one crop or another. On average, hourly wages are higher in the northern region than in the central and southern regions. This is true also by sectors. The average hours worked in the field by a worker in a week are 43. Workers in the border states work about an hour more, whereas workers in the south work about an hour less. The same findings stand out looking by sectors. Women are more involved in agricultural activities in the north, than in the center, than in the south. About 44 per cent of the workers have not completed primary school, this percentage being higher for the south.

4 EMPIRICAL ANALYSIS

Using a reduced-form approach, I investigate whether border price changes, are associated with shifts in agricultural wages and employment.

¹¹Wages are deflated using the CPI from Banco de Mexico with base year 1994. Hence, 10.4 Mexican pesos converts to about US\$1.

4.1 Wages

First, I consider the impact of NAFTA-induced price changes on hourly wages of workers in different crops, k . In the presence of barriers to workers' mobility, or crop-specific skills, or rents enjoyed by workers owing to imperfect competition, there would be wage effects. In particular, price movements for crop k , which move the derived demand function for hired workers in sector k , would positively affect wages in sector k . Hence, there would be a positive relationship between price and wage changes in sector k . Absence of such patterns would indicate that NAFTA had no significant impact, as such barriers or rents do not exist. Furthermore, this finding would be corroborated if employment shifted across sectors according to changes in relative border prices.

To measure the effect of a price change of crop k as well as of price change of crop $j \neq k$ on the wage of a worker in crop k , I should estimate:

$$w_{imt}^k = \alpha_0 + P_t^k \alpha_1^k + \sum_{j \neq k} P_t^j \alpha_1^j + X_{imt} \alpha_2 Z_{mt} \alpha_3 + v_{imt} \tag{1}$$

where w_{imt}^k is the hourly log wage of worker i working in production of crop k , in municipality m , at time t . P_t^k and P_t^j are the log border prices of crop k and $j \neq k$, respectively. The crops considered in the analysis are corn, fruits and vegetables. X_{imt} is a vector of worker characteristics, which include gender, age, marital status and education level. Z_{mt} is a vector of municipality characteristics, which include average land size and technology indicators (e.g. irrigation, machinery and animals), and v_{imt} is an individual error.

However, in Equation (1), border prices are explanatory variables measured at a higher level of aggregation than the dependent variable. This does not allow me to control for yearly effects that could affect wages. Therefore, the estimate of α_1^k would measure the impact of many other variables that could be changing yearly, other than prices. Consequently, it is necessary to take into account errors that are common to observations sharing the same aggregate value. Furthermore, this specification would cause to add built-in correlation between the dependent and the explanatory variables when deflating both wages and border prices to control for inflation. The optimal way to adjust for common group effects, given the data (wherein the number of groups/years, t , is small (8) and the number of observations per year is large) is to follow the two-step procedure as in Donald and Lang (2008). The authors show that the two-step estimation is fully efficient even when the number of groups is small (8 in our case). In addition, this procedure allows me to assess the real impact of NAFTA-induced border price changes on wages. In the first step, I regress wages on year dummies, Γ_t^k , and workers and municipality characteristics with OLS:

$$w_{imt}^k = \Gamma_t^k \Lambda_t^k + X_{imt} \alpha_2 + Z_{mt} \alpha_3 + \xi_{imt} \tag{2}$$

where

$$\Lambda_t^k = \alpha_0 + P_t^k \alpha_1^k + \sum_{j \neq k} P_t^j \alpha_1^j + \varepsilon_t \tag{3}$$

ε_t is a yearly error term, and ξ_{imt} is an individual-specific term that is independent of the other errors. I include municipality fixed effects in the regressions to account for omitted time-invariant municipality characteristics.

In the second step, I regress use as dependent variable the estimates of the year dummy coefficients, $\hat{\Lambda}_t^k$, obtained from the first step, and I regress them on the deflated (to correct for the inflation trend) yearly border prices using OLS:

$$\hat{\Lambda}_t^k = \beta_0 + P_t^k \beta_1^k + \sum_{j \neq k} P_t^j \beta_1^j + \varepsilon_t + (\hat{\Lambda}_t^k - \Lambda_t^k) \tag{4}$$

Therefore, the strategy consists of estimating the effect of each year on wages separately and then regressing these coefficients, $\hat{\Lambda}_t^k$, on the crop prices. β_1^k and β_1^j are the coefficients of interest. They measure how much of the yearly changes in wages can be explained by NAFTA-induced border price changes.

I also perform this analysis at the regional level, dividing Mexican states into three groups: border, central, and southern states.¹² States far away from the border might be less affected by trade liberalisation because goods that are traded in well-connected regions are not necessarily traded in other regions. Furthermore, differences in the quality of soil as well as distance and connection to the US border might be important. In particular, border states have mostly arid land that can be used for corn, whereas southern and central states have a soil that is more suitable for all types of agricultural purposes. However, the southern states have much higher transportation costs than do the border and central states because of the radial structure of highways and railways in Mexico. In fact, all of the commodities coming from the south and directed to the US border must pass through the center of Mexico. Finally, ferry transportation, which would allow for a more rapid connection, is not well developed.¹³ Thus, I expect border states to have been affected by the reduction in corn prices, and central states to have been more influenced by trade liberalisation in all agricultural goods.

4.2 Employment

A similar two-step procedure is applied for employment, with some important differences. I use as employment measure the fraction of hours spent working on crop k , in municipality m , year t :

$$H_{mt}^k = \frac{\sum_i h_{im}^k}{\sum_i h_{imt}} \tag{5}$$

The nature of the data makes this the relevant measure. Given that I do not have a panel but rather, repeated cross-sections, I am not able to observe individual changes in the sector of employment or in the number of hours worked in a given sector. Therefore, I cannot use any variable at the individual level. The alternative is to use an employment measure at the municipality level. I could use either the fraction of workers employed in each sector or the fraction of hours worked in each sector. However, the first measure has one disadvantage.

¹²Border states are as follows: Baja California, Chihuahua, Coahuila, Nuevo Leon, Sonora and Tamaulipas. Central states are the following: Aguascalientes, Baja California Sur, Colima, Distrito Federal, Durango, Estado de Mexico, Guanajato, Hidalgo, Jalisco, Michoacan, Morelos, Nayarit, Puebla, Queretaro, San Luis Potosi, Sinaloa, Tlaxcala and Zacatecas. Southern states are as follows: Campeche, Chiapas, Guerrero, Oaxaca, Quintana Roo, Tabasco, Veracruz and Yucatan.

¹³Detailed descriptions of the differences between border, central and southern Mexican states can be found in Levy (2004) and Levy *et al.* (2002).

If an increase in labour demand in a given sector causes only an increase in the hours worked by each individual in that sector, no change would be observed in the fraction of workers employed, although the fraction of hours worked in that sector would increase. Thus, I choose as employment measure H_{mt}^k , the fraction of hours spent working on crop k in municipality m .

To measure the effect of a price change for crop k as well as of price change for crop $j \neq k$ on employment in sector k , I should estimate:

$$H_{mt}^k = \gamma_0 + P_t^k \gamma_1^k + \sum_{j \neq k} P_t^j \gamma_1^j + W_{mt} \gamma_2 + v_{mt} \tag{6}$$

where H_{mt}^k is the fraction of hours spent working on crop k in municipality m , at time t . P_t^k and P_t^j are the log border prices of crop k and $j \neq k$, respectively. The crops considered in the analysis are corn, fruits and vegetables. W_{mt} is a vector of municipality characteristics, which include gender composition, average age and education level, average land size and technology indicators (e.g. irrigation, machinery and animals), and v_{mt} is an individual error.

As for wages, however, Equation (6) does not allow me to control for yearly effects that could affect employment because border prices are explanatory variables measured at a higher level of aggregation than the dependent variable. Therefore, the estimate of γ_1^k would measure the impact of many other variables that could be changing yearly, other than prices. Thus, to assess the real impact of NAFTA-induced border price changes on employment, I follow a similar two-step procedure to the one outlined above for wages.

Other important issues are worth mentioning. Municipalities in which no one works in crop k have $H_{mt}^k = 0$, whereas municipalities in which all workers are employed in crop k have $H_{mt}^k = 1$. Given that a high number of municipalities do not have at least one worker per crop k (more than 2 per cent), I use a tobit regression with left censoring. Also, for the fraction of hours spent working in corn fields, $H_{mt}^{k=corn}$, I use a tobit regression with left and right censoring because more than 10 per cent of the values are equal to one. Furthermore, I use the number of workers as municipality weight.

In the first step, I regress the fraction of hours spent in crop k on year dummies, Γ_t^k , and municipality characteristics, with a tobit regression:

$$H_{mt}^k = \Gamma_t^k \Theta_t^k + W_{mt} \gamma_2 + \eta_{mt} \tag{7}$$

where

$$\Theta_t^k = \gamma_0 + P_t^k \gamma_1^k + \sum_{j \neq k} P_t^j \gamma_1^j + \mu_t \tag{8}$$

μ_t is a yearly error term, and η_{mt} is a municipality-specific term that is independent of the other errors.

In the second step, I use OLS to regress the estimates of the year dummy coefficients on yearly border prices that have been deflated to correct for the inflation trend.

$$\hat{\Theta}_t^k = \delta_0 + P_t^k \delta_1^k + \sum_{j \neq k} P_t^j \delta_1^j + \mu_t + (\hat{\Theta}_t^k - \Theta_t^k) \tag{9}$$

δ_1^k and δ_1^j are the coefficients of interest. They measure how much of the yearly changes in the fraction of hours spent in a given crop can be explained by price movements.

For both wages and employment, the coefficients of interest are identified with the assumption that unobserved yearly aggregate variables that affect wages are uncorrelated with border prices. This same analysis also is performed at the regional level.

Table 2. Two-step procedure for workers' hourly wages in Mexico

First stage: workers' hourly wages on year dummies			
Hourly wages	Corn	Vegetables	Fruits

4.3 Results

Tables 2–5 present the estimates of the two-step procedure for the effect of NAFTA-induced changes in real border prices of crops on agricultural wages in Mexico, and border, central and southern states, respectively. Considering the first step, for all crops, the year dummy coefficients show an increasing trend because of inflation.¹⁴ Considering the second step, the

¹⁴The omitted year is 1997.

coefficients measuring how much of the yearly changes in the hourly wages can be explained by price movements do not manifest a specific pattern, and none of the coefficients, for any sector, are significant. These findings tend to indicate that changes in the real price of crops did not cause a statistically significant impact on agricultural wages.

Tables 6–9 show the estimates of the two-step procedure for the effect of NAFTA-induced changes in real border prices of crops on agricultural employment in Mexico and border, central and southern states, respectively. In the first step, no particular yearly trend stands out. The second step regression for Mexico as a whole, which is presented in the bottom part of Table 6,

shows that most of the coefficients have the expected sign (i.e. the estimates of δ_1^k are positive), whereas the ones of δ_1^j are negative. This tends to indicate that yearly changes in the fraction of hours spent in crop k are affected positively by a change in the real border price of crop k and negatively by a change in the real price of any other crop. However, at the national level, none of the coefficients are statistically significant. Nevertheless, the analysis at the regional level shows some statistically significant effects. Results from the second step for border and central regions, which are reported in the bottom of Tables 7 and 8, show that NAFTA-triggered border prices significantly affected agricultural employment. First, changes in the real price of

corn positively influenced the fraction of hours spent in corn at the municipality level in both border and central regions, where the impact is larger in the border states. Given the NAFTA-induced reduction in the real price of corn, as found in McMillan *et al.* (2006) and Prina (2011), this finding tends to indicate that corn employment decreased in both regions and by more in the border area. Second, in the central states, variation in the real price of tomatoes positively affected the fraction of hours spent in vegetables. Because the real price of tomatoes increased because of trade liberalisation (Prina, 2011), this result tends to indicate that the fraction of hours spent in the vegetable sector increased in the central region. Third, in the border states, the increase in the real price of tomatoes induced by NAFTA seems to have caused

a reduction in the fraction of hours spent cultivating corn and fruits. Finally, as the results from the second step of Table 9 show, I do not find any significant effect in the southern regions.

The estimated employment effects are statistically significant. The results show some evidence supporting that trade liberalisation in agricultural goods seems to have increased employment in the cultivation of vegetables (main agricultural export) and reduced it in the cultivation of corn (main agricultural import). This is in line with the predictions of neoclassical trade theory: factors seem to have moved smoothly from import-competing sectors into export-competing sectors.¹⁵

¹⁵I also tried to test the presence of local markets. To do so, I regressed hourly wages and hours worked, averaged at the municipality level, on the interaction between crop prices and the fraction of land allocated to each crop in a given year. However, the results were not robust to the functional form.

Regional differences turn out to be important, and the results seem consistent with the regional differences in soil quality and connection to the US border.

5 CONCLUSIONS

The weak or absent response of wages and employment in the manufacturing sector to trade reforms has been motivated by the presence of labour regulations that inhibit both labour mobility and wage flexibility and by the presence of imperfect competition. These explanations do not seem plausible for the agricultural sector characterised by many

farmers and low barriers to entry, where most contracts are informal and most workers are temporary. This paper considers the agricultural labour market in Mexico and measures the impact of NAFTA-induced border price changes of Mexican imports and exports on wages and employment of agricultural workers in Mexico.

The findings show that NAFTA-induced border price changes do not seem to affect agricultural wages. Absence of an effect on wages tends to signal that barriers to workers’ mobility or rents do not exist. This result is corroborated by the evidence that NAFTA-induced border price changes affected employment in the border and central regions. In fact, the NAFTA-induced drop in the price of corn seems to have decreased employment

in the corn sector in both border and central regions and yet more so in the border region. Also, the NAFTA-induced increase in the price of tomatoes seems to have raised employment in the vegetable sector in the central states and decreased employment in the corn and fruit sectors in the border states. Overall, these results are consistent with a standard competitive market with easy mobility across sectors and lack of crop-specific skills, such as the agricultural labour market where tasks are mostly unskilled, and there is little likelihood of sector-specific or crop-specific skills. In fact, the results seem to suggest that there is some mobility across agricultural sectors causing employment in k to be positively affected by price changes in k and negatively by price changes in $j \neq k$.

The results from the analysis at the regional level are consistent with those by Hanson (2006) on the distribution of labour income across regions of Mexico during the country's globalisation in the 1990s. Hanson considers the border and central states to have high exposure to globalisation¹⁶ and the southern states to have low exposure. He finds that labour income in low-exposure states fell relative to high-exposure states by 10 per cent. Finally, these findings also are in line with evidence from Prina (2011) related to farmers' incomes. She finds an impact of agricultural trade liberalisation on the income of farmers working in the border and central states of Mexico and finds no effect for southern states.

ACKNOWLEDGEMENT

First and foremost, I would like to thank Dilip Mookherjee for his continuous guidance and support. Special thanks to Nava Ashraf and Margaret McMillan for sharing their data and to Juan Carlos Torres of INEGI for tireless data assistance.
